Abstract

Intuitionistic logic is conventionally presented as a weakening of classical logic — the removal of excluded middle, the failure of double negation elimination. We argue that this framing is precisely backwards. Intuitionistic logic, properly understood, is the stronger and more discriminating system: it refuses the Boolean collapse that conflates two genuinely distinct operations, which we call complement (not) and opposition (neg). We develop a two-negation framework in which both operators are genuine involutions connected by a Galois connection, and show that the Boolean case — classical logic — is the degenerate special case in which the two coincide. Gödel's double-negation translation is reread as evidence that classical logic is a quotient of two-negation logic, not a generalisation. The misnomer 'intuitionistic' is examined: we argue that Boolean/complement thinking is the intuitive move, and that genuine two-negation thinking — computing the antipode rather than merely the complement — is the counter-intuitive and genuinely constructive one. Social and political examples illustrate that conflating complement with antipode is not merely a logical error but a failure mode with measurable consequences: coalitions built on shared opposition rather than shared values construct nothing and collapse predictably once the common opponent is removed. The paper closes with forward pointers to geometric and physical applications in the companion papers.

Preface: A Correction and Its Consequences

This paper begins with a correction. The correction is small — a renaming, a reframing, a refusal to accept a century-old description at face value. But corrections of this kind are occasionally the most productive moves in mathematics and science, because they remove an obstruction that has been quietly taxing understanding across every domain that inherited the confusion. What follows is an attempt to collect that tax refund.

The correction concerns negation. Classical logic has one negation. The logic conventionally called intuitionistic has, in its standard presentation, a weakened negation — one that fails to be an involution. We propose instead to work with two negations, both genuine involutions, connected by a Galois connection. The Boolean case — classical logic — is recovered when the two coincide. The general case is richer, and it is the general case that turns out to be the natural one.

The naming error — calling the general case 'intuitionistic' and the degenerate special case 'classical' — has had consequences. It has made the Boolean collapse look like the natural default and the escape from it look like a philosophical commitment. It has obscured the fact that three of the deepest results of twentieth-century logic and computation — Gödel's incompleteness, Turing's undecidability, and the simple observation that any honest finite agent sometimes says 'I don't know yet' — all point toward the same conclusion: the Boolean collapse is the special case, not the general condition. And it has hidden the fact that the genuinely constructive mode of reasoning — the one that actually builds something durable — requires the full two-negation geometry, not its Boolean shadow.

This paper makes the correction precise and traces its immediate consequences in logic, algebra, and cultural reasoning. But the correction has a longer reach. The companion papers in this series follow it into geometry, physics, thermodynamics, and topology, finding in each domain new clarity that was latent in the structure all along, obscured by the inherited confusion. The programme is not five papers on related topics. It is one correction and its consequences.

Paper 0 (this paper) diagnoses the error, corrects it, and shows that the Boolean collapse is not constructive — in mathematics, in logic, or in the social and political domains where its consequences are most visible. **Paper 1** follows the correction into the foundations of geometry and physics, deriving relativistic uncertainty and the structure of measurement from the causal skeleton alone. **Paper 2** follows it into thermodynamics, finding that temperature is a primitive scalar field conjugate to curvature, and that the Unruh effect and the Hawking temperature are geometric results requiring no quantum field theory. **Paper 3** follows it into topological dynamics, connecting vorticity, helicity, and curvature rotons in a unified non-ecological framework. **Paper 4** closes the loop with Noether's theorem: every symmetry generates a conserved quantity; every coupling generates an uncertainty relation; and the action, read as the dissipative cost of a path, is the receipt for the trajectory.

The reader who finds the logical argument of this paper compelling is invited to follow it wherever it leads. The landscape is larger than it appears from the entrance, and the view from the other side of the correction is considerably clearer.

The correction described in this paper required no new mathematics. It required only noticing, carefully, that a choice was being made where none appeared to be — and asking what would happen if the choice were made differently. The answer, it turns out, is: quite a lot.

1. The Misnomer and Its Consequences

Brouwer introduced intuitionistic logic as part of a broader philosophical programme: mathematics should be grounded in mental construction, infinite objects should not be treated as completed totalities, and a proof of existence should exhibit the thing it claims to exist. The logic that formalises this programme — developed by Heyting — bears the name 'intuitionistic' in honour of Brouwer's intuitionism.

The name has caused a century of confusion. It suggests that the logic is somehow more intuitive than classical logic, or that it captures mathematical intuition more faithfully, or that it is the natural starting point from which classical logic is obtained by adding further axioms. None of these are true. Intuitionistic logic is in fact the counter-intuitive logic — the one that resists the first and most natural move. And it is not obtained from classical logic by removing axioms; rather, classical logic is obtained from two-negation logic by collapsing a distinction.

1.1 The intuitive move

The intuitive move, in both mathematics and everyday reasoning, is the Boolean collapse: treat 'not' as the only negation, identify the complement of a set with its opposition, assume that the enemy of one's enemy is one's friend. This is the move that feels natural, that requires no additional data, that works without effort in a two-valued world.

It is also, in any world richer than two points, frequently wrong. The complement of a set and its antipode — the set of elements genuinely most distant from it — are not the same thing. Identifying them is an error, and the consequences of the error are visible at every scale from logic to politics.

1.1b The naming failure runs deeper

The catastrophe of the naming runs deeper than it first appears. At least three routes out of the Boolean collapse present themselves before any formal logic is encountered. First, the child's response: *I don't know yet*. This is the most naively intuitive epistemic state of any finite agent in a world where information arrives over time. It is more intuitive than classical logic, more intuitive than so-called intuitionistic logic, and it is the actual starting point for any honest reasoner. Temporal logic, epistemic logic, and probability theory are all formalisms built around this observation — none of them are called intuitionistic.

Second, Gödel's incompleteness theorems — the mathematical third way. There exist propositions that are neither provable nor refutable within a given sufficiently rich system. This is not a philosophical programme or a failure of nerve; it is a theorem. The Boolean collapse is provably unavailable from the inside of any system powerful enough to be interesting. Gödel's result is more radical than Brouwer's: it shows that the two-colour geometry fails mathematically, not merely philosophically.

Third, Turing's halting problem — the computational third way. There exist computations whose termination cannot be decided in advance. The answer to 'does this program halt?' is not true or false but *undecidable* — and undecidability is not ignorance but a provable structural feature of computation. Turing shows that the Boolean collapse fails computationally: any system powerful enough to be interesting is powerful enough to escape the two-colour geometry.

All three of these — I don't know yet, Gödel incompleteness, Turing undecidability — are more intuitive than anything in Brouwer's constructivist programme, and all three motivate the same conclusion: the Boolean collapse is the special case, not the general condition. Yet none of them are called intuitionistic. The name was captured by one specific philosophical escape route, making all the others invisible and making the collapse itself look like the natural default. It is catastrophically badly named.

1.2 What the name should be

We propose throughout this paper to call the logic in question **two-negation logic**. This has the considerable virtue of describing what the logic actually contains: two genuine negation operators, both involutions, connected by a Galois connection, whose coincidence is the Boolean special case and whose distinctness is the general case. No philosophical programme is implied, no claim about mental construction is smuggled in, and no misleading suggestion of naturalness or intuition is conveyed. The name is what the thing is.

2. Two Negations

We operate not on truth values but on **propositions** — or more precisely, on the classification of sentences according to their propositional status. The three values are not degrees of truth but categories: 1 for true propositions, -1 for false propositions, and 0 for sentences that are not yet — or not even — propositions susceptible to truth or falsity. The third way is not an unknown truth value; it is the **absence of propositional status**. A sentence in the third way has not failed to be true or false — it has not yet achieved the level of determinacy at which truth or falsity applies.

This reframing is not merely philosophical. It explains directly why the order-reversing property holds within each category but not across the category boundary. The sets $\{0\}$ and $\{-1,1\}$ are not comparable by inclusion because they inhabit different layers of the logical hierarchy: one classifies propositional status, the other classifies truth value. The order-reversing failure of neg is not a defect but a diagnostic — it marks precisely where the category boundary lies.

We work in the powerset $P(\{-1,0,1\})$, ordered by inclusion. The universe is $U = \{-1,0,1\}$. Both not and neg are functions on the full powerset — we list their values on singletons for illustration, but the operators are defined on all eight subsets.

2.1 The complement

not(A) denotes the complement of A in U: the set of all elements of U not in A. This operator is free — it requires no additional data beyond U itself. It is an involution: $\text{not}(\text{not}(A)) = A$. It is order-reversing: if $A \subseteq B$ then $\text{not}(B) \subseteq \text{not}(A)$. In the Boolean case — $|U| = 2$ — it is the unique non-trivial involution.

2.2 The antipodal operator

neg(A) denotes the antipodal set of A: the set of all elements of U maximally distant from A, in some specified sense of opposition. This operator is costly — it requires additional data: a metric, a convex hull, an antipodal map, or some other specification of what counts as maximal distance in U. It is also an involution and order-reversing, but it is not, in general, equal to not.

The additional data required to specify neg is precisely the semantic data — the information about the geometry of U that goes beyond its bare set-theoretic structure. Complement is syntactic; opposition is semantic. This distinction is the logical form of the syntax-semantics gap identified by Lawvere, and it runs through every application in the companion papers.

2.3 The explicit three-value model

The following explicit model on $P(\{-1,0,1\})$ instantiates the framework. Both not and neg are defined on all eight subsets; we list them top to bottom (full universe to empty set):

not: $\{-1,0,1\} \rightarrow \emptyset$, $\{-1,0\} \rightarrow \{1\}$, $\{-1,1\} \rightarrow \{0\}$,
 $\{0,1\} \rightarrow \{-1\}$
 $\{-1\} \rightarrow \{0,1\}$, $\{0\} \rightarrow \{-1,1\}$, $\{1\} \rightarrow \{-1,0\}$,
 $\emptyset \rightarrow \{-1,0,1\}$
neg: $\{-1,0,1\} \rightarrow \emptyset$, $\{-1,0\} \rightarrow \{1\}$, $\{-1,1\} \rightarrow \{0\}$,
 $\{0,1\} \rightarrow \{-1\}$
 $\{-1\} \rightarrow \{1\}$, $\{0\} \rightarrow \{-1,1\}$, $\{1\} \rightarrow \{-1\}$,
 $\emptyset \rightarrow \{-1,0,1\}$

The operators agree everywhere except at the Boolean singletons: $\text{not}(\{-1\}) = \{0,1\}$ while $\text{neg}(\{-1\}) = \{1\}$, and $\text{not}(\{1\}) = \{-1,0\}$ while $\text{neg}(\{1\}) = \{-1\}$. neg strips 0 from the output of not on definite propositions — it maps to the genuine opposite without admitting the third way as an output. Verified properties: not is an involution; neg is a deflation ($\text{neg}(\text{neg}(S)) \subseteq S$); non-contradiction holds; excluded middle fails for neg (the third way exists); both Galois conditions hold; $\text{not} \neq \text{neg}$. The order-reversing property holds within each propositional category but fails across the category boundary — specifically at $\{-1,1\}$, whose neg lands in the orthogonal third-way category $\{0\}$.

2.4 The Galois connection axioms

We take as fundamental:

$$A \subseteq \text{not}(\text{neg}(A))$$

$$\text{neg}(\text{not}(A)) \subseteq A$$

The first: nothing is its own antipode — no element is maximally distant from the set it belongs to. The second: the antipode of the complement is already inside A — the deepest interior of A in the antipodal sense is contained in A. These two axioms are not independent: given that both operators are order-reversing involutions, each implies the other. Together they express precisely that not and neg form a **Galois connection** — neg is the right adjoint of not in the poset $P(U)$ ordered by inclusion.

2.4 The Boolean collapse

When $|U| = 2$, there is only one non-trivial involution on U. Both not and neg must be this involution. They coincide necessarily — not by choice or approximation, but by the geometry of the space. The Galois connection degenerates to an isomorphism. Complement and opposition are identical. This is classical logic.

Classical logic is therefore not the general case with intuitionistic logic obtained by restriction. It is the degenerate special case — the one in which the space is so impoverished that the two negations cannot be distinguished. Two-negation logic is the general case; classical logic is its Boolean shadow.

2.5 Structural consequences

The compositions $\neg \neg$ and $\neg$ not become, respectively, a closure operator and an interior operator on $P(U)$. Their difference — the gap between closure and interior — is the boundary in the topological sense: the region where the two negations fail to agree, the locus of genuine logical indeterminacy. In the Boolean case this boundary is empty. In richer spaces it is where the interesting content lives.

The underlying algebraic structure connects to bi-Heyting algebras and orthocomplemented lattices, though the specific combination of two genuine involutions connected by a Galois connection does not correspond exactly to any single well-studied structure. The free algebra on a set of generators, the appropriate notion of morphism, and the relationship to topos theory remain open questions.

3. The Boolean Collapse and Its Cultural Instantiations

The Boolean collapse is not merely a logical curiosity. It is a failure mode with measurable consequences whenever reasoning takes place in a space richer than two points but is conducted as if the space had only two values.

3.1 Political coalitions

A recurring pattern in the aftermath of revolutions and referenda is the rapid dissolution of coalitions that appeared, during the campaign, to be unified and purposeful. The Brexit alliance, various revolutionary coalitions, and numerous electoral upsets share a common structure: many individuals persuaded themselves that they had much in common with many other people, on the basis of shared opposition to a common target. Complement was computed when antipode was required.

In a two-colour political geometry — pure binary opposition — this error is not merely easy to make but structurally enforced. If the space of political positions is genuinely two-valued, then everyone not-X really is in the same position, and the complement of X really is a coherent coalition. The error lies not in the logic but in accepting the two-colour geometry — in allowing the richness of the actual space to be collapsed to a Boolean shadow before the computation begins.

The two-party system enforces this collapse institutionally. It does not merely encourage the conflation of complement and antipode; it makes the distinction formally unavailable. This is not a contingent feature of any particular political culture but a provable consequence of the geometry: in a two-element set, there is only one involution.

3.2 The enemy's enemy

The common political heuristic — my enemy's enemy is my friend — is the Boolean collapse stated as a decision rule. It computes $\neg(\neg(\text{me}))$, which in classical logic returns the identity, and interprets this as a positive alignment with everyone in $\neg(\neg(\text{me})) = \text{me}$'s vicinity. But what is actually required is $\neg(\neg(\text{me}))$ — the antipode of the antipode, which also returns to

me, but via a path through genuine shared values rather than shared opposition.

In a two-element set these coincide. In any richer space they need not — and the gap between them is precisely the space of people who oppose your enemy for entirely different reasons, with entirely different values, and who will become your next problem the moment the shared enemy is removed. The heuristic is a reliable guide only in a Boolean world. Applied in a richer space, it constructs nothing.

3.2b The third way: not even a statement

The third way has been discovered and rediscovered across every domain of human inquiry, always named differently, never unified. The unifying description, in the light of the propositional status framing, is: *not even a statement* — a sentence that has not achieved the level of determinacy at which true or false applies.

In everyday epistemology: *I don't know yet* — the question has not been pinned down to a determinate proposition. In linguistics: *meaningless* or *category error* — literally not a well-formed proposition. In formal logic: *undecidable* — not reachable by proof or refutation. In proof theory: *unprovable* — outside the deductive reach of the system. In quantum mechanics: *unmeasured* — no eigenvalue until measurement forces propositional status. In relativistic measurement: *pre-measurement indeterminate* — no fact of the matter accessible within the causal structure. In computation: *non-terminating* — the program never produces a value, hence never achieves the status of a completed proposition. In ecology: *ecologically unspecified* — no instantiation of the semantic data has been chosen.

Every entry in this list is a domain-specific way of saying the same thing: this has not yet achieved propositional status. The Boolean collapse destroys the category by forcing every sentence into true-or-false before the question of propositional status has been settled. This is not rigour — it is premature closure.

3.3 Complement is not constructive

This is the central observation of this section, and the deepest irony of the naming. Brouwer called his logic 'constructive' because it required proofs to exhibit their objects. But in the social and political domain, it is precisely the Boolean/complement mode of reasoning that is destructive in the ordinary sense: it builds coalitions out of shared opposition rather than shared values, it constructs nothing that survives the removal of the common enemy, and it collapses predictably once the Boolean geometry can no longer be sustained.

Two-negation thinking — actually computing the antipode, actually identifying who shares your deepest values rather than merely your current opponent — is the genuinely constructive mode. It is harder. It requires the full metric of the space, the additional semantic data that specifies what opposition actually means in the geometry at hand. It cannot be done in a Boolean world. But it builds something that persists.

In Gretzky's formulation: skate to where the puck is going to be, not where it is. The Boolean reasoner skates to where the puck's complement is. The two-negation reasoner skates to the antipode. Only one of these is a coherent destination.

4. Gödel's Evidence

The strongest evidence that classical logic is a quotient of two-negation logic rather than a generalisation comes from Gödel's 1933 double-negation translation.

4.1 The translation

Gödel showed that every classically provable proposition A can be translated into an intuitionistically provable proposition A^* by prefixing double negations at appropriate positions. The map $A \mapsto \neg\neg A$ is the simplest instance: if A is classically valid, then $\neg\neg A$ is intuitionistically valid. Classical logic embeds faithfully into intuitionistic logic via this translation.

The direction of the embedding is decisive. Classical logic goes *into* intuitionistic/two-negation logic, not the other way around. Two-negation logic is the larger system; classical logic is a quotient obtained by identifying not with neg — by forcing the Galois connection to be an isomorphism.

4.2 Reread in our framework

In our two-negation framework, the double-negation translation has a transparent interpretation. The map $A \mapsto \text{not}(\text{not}(A))$ is the identity in the Boolean case, because not is an involution. But the map $A \mapsto \text{not}(\text{neg}(A))$ — complement of the antipode — is the closure operator, which is not the identity in the general case. The Gödel translation is computing the closure, not the identity: it is mapping each proposition to its classical shadow in the two-negation geometry.

This makes the translation's direction natural: the classical shadow of a two-negation proposition is always well-defined (the closure always exists), but the two-negation content of a classical proposition is not (the closure does not uniquely determine the original). Information is lost in the passage to the Boolean quotient, and the Gödel translation is the canonical way of recovering the two-negation proposition from its classical shadow — at the cost of introducing explicit closure operators.

4.3 What Gödel knew

Gödel did not frame his result in these terms, but the implication is clear: the so-called intuitionistic logic is the more expressive system. It distinguishes things that classical logic identifies. It preserves information that classical logic discards. Calling it intuitionistic — suggesting it is somehow less rigorous, less complete, less general than classical logic — is precisely backwards. It is the richer geometry. Classical logic is its Boolean shadow.

5. Lawvere and the Syntax-Semantics Adjunction

The deepest motivation for the two-negation framework comes from Lawvere's observation that syntax and semantics are adjoint functors. In categorical logic, the passage from a theory (syntax) to its models (semantics) and back is not an isomorphism but an adjunction — the two levels are optimally related without being identical.

Our two operators instantiate this at the set-theoretic level. **not** is the syntactic operator: free, structural, requiring no interpretation, available from the bare universe U . **neg** is the semantic operator: requiring additional data, a specification of what opposition means in the geometry of U , the antipodal map that gives the syntax its meaning in a particular world.

The Galois connection between not and neg is the syntax-semantics adjunction, made concrete and local. The amount of data required to specify neg is precisely the amount of work required to provide a semantic interpretation for a given syntax. In the Boolean case this work vanishes: the two-element universe has only one possible involution, the semantics is forced by the syntax, and logic is classical. In richer settings the antipodal map is an additional free choice, and different choices yield different meanings for the same formal language.

5.1 The cost of semantic data

This observation — that neg requires additional data while not does not — connects directly to the thermodynamic framework of Paper 2. The data required to specify the antipodal map is ecological data in the sense of Paper 1: it is not forced by the structural mathematics but is an additional choice, a commitment to a particular world. Different antipodal maps give different logics — or equivalently, different meanings for the same formal language.

The cost of that additional data — the price of specifying neg rather than merely using not — is the thermodynamic cost of instantiating a particular semantic interpretation. This is the Landauer-Vaccarino-Barnett accounting applied to logic: the semantic operator costs something, and that cost is denominated in the conjugate variable to whatever quantity the antipodal map is measuring.

5.2 The theorem of ecological uncertainty

The Galois connection between not and neg generates a conjugate pair in the sense of the theorem developed in Paper 1:

Theorem (ecological uncertainty). Let x and y be quantities governed by reciprocally coupled equations — each appearing as a source term in the other's dynamics. Then the product of their measurement uncertainties is bounded below by a constant determined by the coupling strength. Simultaneous exact determination of x and y is structurally impossible, independently of the domain.

In the logical setting: not and neg are reciprocally coupled via the Galois connection. You cannot simultaneously determine the complement and the antipode of a set to arbitrary precision — knowing one constrains the other, and the constraint is the adjunction constant. The uncertainty relation is the Galois connection, expressed epistemically.

6. Forward Pointers to the Companion Papers

The two-negation framework developed here is not isolated. It reappears, in geometric and physical guise, throughout the companion papers. We sketch the connections briefly, reserving full development for the papers themselves.

6.1 Paper 1: Syntax, Geometry, and Measurement

The not/neg distinction reappears at every level of the informational axiomatisation of relativity. The causal order and cone structure (Levels 0-1) are the syntactic skeleton — free, structural, assumption-free. The metric, curvature field, and matter content are the semantic superstructure — requiring additional ecological data. The field equations are the Galois connection. The flat Minkowski metric of SR is the Boolean collapse in geometric form: the special case where syntax and semantics coincide and the geometry appears to need no explanation.

The relativistic uncertainty of Paper 1 Section 4 — derived from the Level 1 causal structure alone, without quantum mechanics — is the first physical instantiation of the theorem of ecological uncertainty. The primacy of expectation values follows: since measurements are irreducibly uncertain, a rational agent can only skate to where the puck is going to be in expectation. This is not a quantum postulate but a relativistic necessity, derivable from the cone geometry alone.

6.2 Paper 2: *Uncertainty and Unruhigkeit*

The not/neg distinction becomes, in the thermodynamic setting, the distinction between causal isolation boundaries (not — the level surfaces of the temperature field, freely determined by the causal order) and curvature sources (neg — requiring ecological specification). Temperature is a primitive scalar field T satisfying $\text{Box}(T) + (1/3)RT = 0$, derived from the free-streaming Liouville equation on the geodesic flow without particle content. The Galois connection between T and R is exact: their level surfaces coincide, their gradients are aligned, and the thermodynamic uncertainty relation $S * T^2 = 1/16\pi$ is identical to the non-ecological Tolman relation $r_{\text{eff}} * T = 1/4\pi$.

Unruhigkeit (restlessness, acceleration) is conjugate to Unruheffekt (the Unruh thermal bath). The title of Paper 2 states its own theorem. The Unruh effect — the universe showing what is being attempted — is the receipt for the semantic fork: the thermodynamic cost of instantiating a particular antipodal map on the causal skeleton.

6.3 Papers 3 and 4 (forthcoming)

Paper 3 extends the framework to topological dynamics: vorticity in fluid mechanics as the analogue of curvature, helicity as gravitational entropy, the Kelvin circulation theorem as the fluid Bianchi identity. Curvature rotons — oscillatory excitations of the curvature field at the characteristic Raychaudhuri focusing scale — may correspond to new vacuum solutions of the Bianchi-constrained dynamics. The Kolmogorov turbulence spectrum is the fixed point of the topological uncertainty relation.

Paper 4 connects to Noether's theorem: every continuous symmetry of the action generates a conserved quantity (Noether); every reciprocal coupling generates an uncertainty relation (our theorem). Noether counts what is free — the forks that cost nothing. Our theorem prices what is not free. The action, read as the dissipative cost of a path, is the receipt for the trajectory. Together the two theorems give a complete accounting of the geometry of dynamical systems.

7. Synthesis: What Two-Negation Logic Actually Is

We are now in a position to characterise two-negation logic precisely, and to explain why the received framing has been systematically misleading.

Two-negation logic is **not** a weakening of classical logic. It is a generalisation — the richer system of which classical logic is the Boolean quotient. It is not obtained by removing excluded middle; rather, excluded middle is obtained by collapsing the two negations into one.

Two-negation logic is **not** the intuitive system. The Boolean collapse is the intuitive move — cheap, effortless, available without semantic data. Two-negation thinking requires resisting the first intuition, paying the cost of the antipodal map, computing in the

full geometry rather than its shadow.

Two-negation logic is **not** merely constructive in Brouwer's mathematical sense. It is constructive in the deeper social and political sense: it is the logic that actually builds something, because it identifies genuine shared values rather than mere shared opposition. Complement is not constructive. Antipode is.

The theorem of ecological uncertainty says that this constructive move always has a cost — denominated in the conjugate variable to whatever the antipodal map is measuring. There is no free lunch in the geometry of opposition. But the cost is worth paying, because what is built survives.

The Galois connection between not and neg is the mathematical form of the gap between syntax and semantics, between structure and ecology, between the cheap and the costly. It runs through logic, geometry, physics, and political philosophy. We have preferred to call the logic that takes this gap seriously two-negation logic. It deserves a better name than the one it has carried for a century.

Acknowledgements. This paper was developed through an extended dialogue between the authors, as the logical foundation of a broader programme. The human author identified the core observation — that intuitionistic logic is misnamed, and that the Boolean collapse is precisely the non-constructive move — in a series of conversations spanning logic, physics, and political philosophy. The Platonic tradition is thanked, as always, for the conversational form.
